INTRODUCTION

Hitney (1992) presented a method to remotely sense the refractivity structure of the troposphere. This method allows the base of a trapping layer to be determined directly from radio measurements. Since radio signal strength can be computed as a function of the trapping layer base height using the Naval Ocean Systems Center Radio Physical Optics (RPO) model, the observed signal strength may be similarly applied to the RPO model to infer the base height.

This method has been applied to the data of a few UHF signals that were recorded in 1945 during the San Pedro-Point Loma experiment (Hitney, 1992, and Anderson, 1944). The 40-day period of continuous radio data and meteorological measurements shows a remarkable negative correlation between the received signal strengths and the base of the temperature inversion. This suggests the base height of the trapping layer, usually associated with a temperature inversion, is an important factor in influencing radio propagation on over-the-horizon paths. Assuming horizontally homogeneous refractivity conditions and a simple tri-linear modified refractivity profile, the RPO propagation model is applied to the 100-MHz and 547-MHz data sets. Such applications result in inferred base heights that compare quite well to the measured base heights, especially for the higher frequency signal. However, the comparison of a few predictions to the measured data set is not a satisfactory validation of the method, nor a confirmation of its limitations. Therefore, this remote sensing technique requires some further investigations.

INVESTIGATION

An experiment has been conducted to sense signal levels of several VHF and UHF paths along the coast of southern California. The sources of these signals are from Automatic Terminal Information Service (ATIS) broadcasts for airports along the southern California coast (table 1). These ATIS sources are selected such that with the

receiver placed at Point Loma (NOSC Building 323), the transmission paths are well beyond the horizon and mostly over water (figure 1). There are 16 ATIS frequencies of interest which range from 117 MHz to 385 MHz. The transmitters are located from 3- to 177-meters above mean sea-level (msl), and they formed transmission paths from 50- to 300-km in length.

RF DATA ACQUISITION SYSTEM

At NOSC, where the radio measurement is recorded, an LP-1019BA log-periodic antenna was mounted for vertical polarization on the roof of Building 323, at about 40 m above msl, and pointed to the northwest (bearing 320°). From there the received RF signal is fed through a 40-foot RG214 coaxial cable and monitored by an HP-8566B Spectrum Analyzer. The HP-8566B's frequency range and sensitivity are fully adequate for detecting the ATIS signals. For automatic data acquisition, the HP-8566B is connected to an 80286 microcomputer via an IEEE 488 bus. A National Instrument GPIB-II IEEE 488 interface board is used to provide software control of the IEEE bus with the microcomputer.

A simple C-Language program (ATIS.C) was developed to monitor the received ATIS signals and to record the signal levels. The program typically sets the HP-8566B's RF input attenuation at 0 dB, center frequency at an ATIS frequency, the frequency span at 10 kHz, with resolution bandwidth at 100 Hz, and video bandwidth at 300 Hz. The analyzer is also programmed to perform video averaging of five sweeps for each signal, to optimize signal detection. For each ATIS signal, its frequency, signal-to-noise ratio (referenced to 100 Hz bandwidth), and propagation loss are recorded with an effective sample time of 15 seconds. For a one-way transmission system, the propagation loss (in dB) is

$$L = P_t + G_t - P_r + G_r + G_c ,$$

where P_t is the power transmitted, G_t and G_r are transmitter and receiver antenna gains, P_r is the signal power received, and G_c is the coax gain measured from the receiver antenna to the RF input of the analyzer. The typical ATIS antenna is omnidirectional and radiates at about 10 watts, making the sum of the first two terms equal to 40 dBm. The high directive gain of the LP-1019BA receiver antenna is about 8 dB, and the cable gain G_c was measured as -1.0 to -2.0 dB. (See table 2.)

In operation, the above measurements are automatically stored on disk files as ASCII text format, for further processing. The measurements are recorded 24 hours per day, at intervals of 15 minutes. The recording began in late September 1991 and is ongoing. However, there are gaps in the data, due to software and hardware failures that were eventually corrected. Table 3 shows the time periods in which measurements were made.

DATA ANALYSIS

As a first step in analyzing the recorded data, we have written a program (PLTATIS.BAS) to graphically present the time-series of observed ATIS signal-to-noise ratio, propagation loss, propagation factor (relative to free space), and inferred trapping layer base height. Figure 2 shows some results from the November 1991 measurement period, indicating the typical variation in signal strengths (associated with the change in trapping layer base height). Notice there are limits for the observed propagation factors (when signal levels are below the noise level), that will also limit the inferred base heights. Determining the trapping layer base height from radio measurements is quite intricate. First, for each of the ATIS paths, the propagation factor must be computed as a function of trapping-layer base height using the RPO propagation model (RPO program).

ATIS 1991: RF Propagation Data

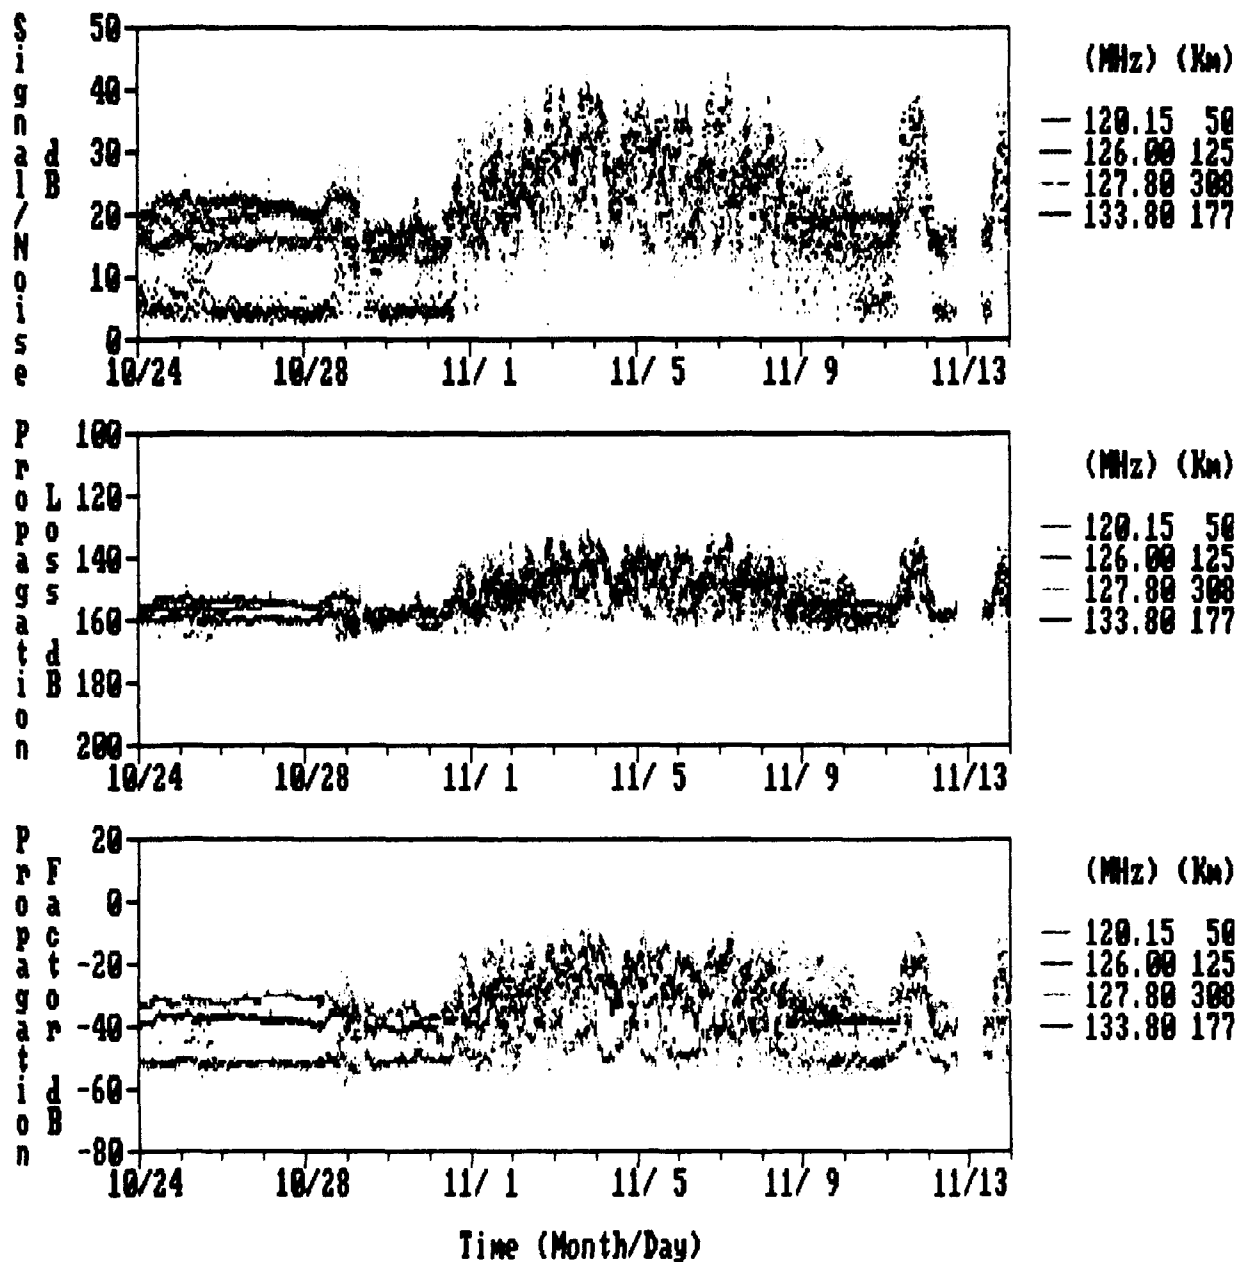

Figure 2. Signal strengths.

Horizontal homogeneity and a simple tri-linear modified refractivity profile, where trapping layer characteristics are derived from historical statistics of the area, are assumed. The tri-linear profile is constructed with a median trapping layer strength of 30 M-units and a thickness of 130 meters. For every value of trapping-layer base heights (0 to 1400 m), the propagation factor calculated by RPO must be read off manually using the EREPS PROPR program. The RPO results for each ATIS frequency are plotted in figures 3a through 3o, and shows propagation factor versus the base of the trapping layer. The line in figures 3a through 3o is an approximate fit through the first several data points (at base heights lower than 800 m); apparently, there is substantial variation between the data points and especially for the higher trapping layer base heights. The linear regression can be characterized by the slope and the y-intercept of the line. These two quantities are tabulated in table 4 and are used (by PLTATIS.BAS) to compute the inferred base heights from observed propagation factors.

RESULTS

Typical time-series plots of inferred base heights, figure 4, show good correlation of temporal variation; ATIS sources near each other give almost the same inferred trapping base heights, especially in the Los Angeles area. However, the inferred base heights also vary extensively for some of the other paths. Such disagreement is perhaps a result of the uncertainty in linear regression of the computed propagation factors versus trapping base heights, because there are substantial deviation errors in the linear approximation. Furthermore, as shown in scatter plots of figure 5, observed trapping base heights generally do not agree with the base heights inferred from the radio data, nor do they agree with each other. This is probably an indication that the assumption of horizontal homogeneity does not always hold.

In any case, additional measured data of base heights are required to verify the extent of any nonhomogeneous condition and to explain the discrepancies between prediction and observation of trapping layer base heights. Thus far in this experiment, the measured data available are from the radiosonde observations of a few World Meteorological Organization (WMO) stations in southern California. Since most of these stations are located away from the transmission paths of interest and their radiosonde observations are sporadically reported, the available data are not reliable or useful.

CONCLUSIONS

A remote sensing experiment has been established to examine the method of determining base heights of a trapping layer directly from VHF and UHF radio measurements. The setup of this experiment is relatively simple and convenient; it uses existing radio broadcasts along the coast of southern California as sources of signal propagation and requires minimal equipment to record the signal strengths of such transmissions.

However, the technique of processing the recorded data to infer trapping layer base heights is somewhat uncertain. The linear formulation of propagation factor as a function of base height from the RPO propagation model is only an approximation; hence, errors are expected in the inferred base heights. In addition, considerations of horizontal homogeneity may be invalid. Further investigation into these problems may provide improvement for the technique. Nevertheless, the experiment shows some strong correlations between the observed signal strengths as well as the inferred trapping layer base heights of the various radio paths, indicating the height of the trapping layer is an important factor in controlling radio propagation on over-the-horizon paths.
